## **ABSTRACT**

Glutaraldehyde (GA) has been used extensively as a biocide in hydraulic fracturing fluids leading to the contamination of the compound in produced water. In this study, the performances of photolysis and photocatalysis for removal of GA in synthetic produced water were investigated. The photolytic degradation rate of GA increased with increasing incident ultraviolet light intensity and decreasing pH. Increasing initial GA concentration resulted in a reduced rate of GA degradation. At high salt concentrations, similar to the levels found in produced water, the photodegradation rate of GA was better than those at zero/low salt concentrations. In photocatalytic experiments, GA could be degraded efficiently under both simulated visible light and natural sunlight. Photolysis and photocatalysis are promising technologies for removing GA in produced water due to their small footprint, ease of operation, and efficiency. This study helps in addressing an obstacle associated with produced water treatment and disposal.

## **ACKNOWLEDGEMENTS**

I would like to express my deepest gratitude to my advisor Dr. Eakalak Khan for all of his guidance, encouragement, support and patience that he offered throughout my study at North Dakota State University (NDSU). I would like to extend my thankfulness to Dr. Jayaraman Sivaguru my co-advisor at NDSU for his support, valuable comments and advice.

I also would like to thank my committee members, Dr. Achintya Bezbaruah and Dr. Om Prakash Yadav, for their constructive comments. I would like to thank the North Dakota Water Resources Research Institute Fellowship program for funding my research. I wish to thank my friends at NDSU for their help, motivation and time to share happiness and joy.

To all the accomplishment, I owe it to my parents and my two little sisters who are always there for me.

## **1. INTRODUCTION**

### **1.1. Background**

In unconventional oil and gas extraction, hydraulic fracturing has been applied to ensure high and prolonged production of oil and gas from low permeability shale deposits. This technology induces cracking network in low-permeability shale to allow trapped oil and/or gas flow to the production wells by injection of hydraulic fracturing fluid at extremely high pressure and flow rate. After hydraulic fracturing process, there are two types of waters discharged from the well along with oil and gas. These waters are flowback water, mostly hydraulic fracturing water, and formation water, naturally occurred shale water. Flowback and formation waters are collectively known as produced water. Hydraulic fracturing fluids are mainly water (98-99%) and proppant (mostly sand, 1-1.9%); however, several chemicals are added to the fluids to increase hydraulic fracturing performance. Among the chemical additives, biocides are one of the most common additives in hydraulic fracturing fluid. After hydraulic fracturing, biocides are also periodically injected to the wellbores. They are used to prevent corrosion to the wells associated with microbial growth.

Biocides are one of the most harmful contaminants in flowback water (King, 2012; PTAC, 2011; Rimassa et al., 2011). Glutaraldehyde (GA), the most common biocide used in hydraulic fracturing fluid, accounts for 80% of all shale fracturing (King, 2012). It is also used regularly to keep the number of bacterial cells low in the production well (Fakhru'l-Razi et al., 2009). GA is classified as a high level disinfectant due to its lethal action against all types of microorganisms (Russell, 1994). Since it is used extensively by the oil and gas industry, large amounts of produced water containing GA are generated. GA is a harmful chemical to the environment, human and aquatic organisms. It is a very strong irritant that can cause severe injuries to eyes, skin and

respiratory tract. In the environment, it is very toxic to aquatic organisms, especially algae, microorganisms, and fresh water fishes (Leung, 2001).

In addition to its toxicity, another obvious issue with GA in produced water is the restriction of biological activities making biological treatment of the produced water a non-viable alternative. In a study of biodegradability of tanning agents, GA at concentrations of 2.5 mg/L inhibited activated sludge process (Sun et al., 2008). Biological treatment (Bioremediation) is the most preferred treatment technology since it is economical and effective against a variety of environmentally harmful chemicals including those in produced water such as gelling agents, surfactants and organic materials. However, GA, the biocide, is the principle compound that limits the application of biological treatment. Thus, removing GA from flowback and produced waters would be beneficial for the environment, and wastewater treatment, recyclability and disposal.

Photolysis has been used to degrade organic contaminants such as pesticides (Burrows et al., 2002) and pharmaceuticals (Yamamoto et al., 2009). Unlike other treatment technologies, photolysis can be used in all media – aqueous, soil and air. All of organic compounds are photodegradable. The technology requires small footprints, and is easy to operate and effective against organic compounds. On the other hand, photocatalysis involves using of photocatalysts that upon irradiating produce reactive species to activate and/or speed up the reaction. Newly developed photocatalysts can be activated by visible light to degrade pollutants that resist to visible light photolysis. Both photolysis and photocatalysis are attractive candidates for treating GA in produced water.

## **1.2. Research objectives**

This study aims to apply an advanced treatment technology which is photodegradation, including photolysis and photocatalysis to remove GA from brine simulating produced water.

The specific objectives of the study are:

- Determine GA removal efficiency and kinetics by photolysis and photocatalysis;
- Investigate the effects of operating conditions on photolysis and photocatalysis of GA; and
- Elucidate removal mechanisms, pathways, intermediates, by-products, end-products of photolysis and photocatalysis of GA.

### **1.3. Hypothesis**

Under UV light at 254 nm, chemical bonds of GA are broken by absorption of the light resulting in the formation of a number of photolytic and photocatalytic intermediates and byproducts that have smaller molecules.

### **1.4. Scope of study**

In photolysis, the effects of light intensity, irradiation time, pH and initial GA concentration were investigated. In photocatalysis, a composite of Ag/AgCl/BiOCl was used as a photocatalyst. The effects of photocatalyst loading, pH, light source, NaCl concentration, and initial GA concentration were investigated in photocatalysis. Brine simulating produced water using NaCl as salt was used. It is possible that intermediate and by-products that have smaller molecules (compared to GA molecules) would be produced by photodegradation. These molecules, which tend to be more biodegradable (more biologically treatable) were identified.

### **1.5. Anticipated results and benefits**

This project helps to address an obstacle associated with produced water treatment and disposal. After removing glutaraldehyde from produced water, biological treatment, which is economical, becomes viable for treatment of the produced water, or it makes the waters less harmful for disposal. The project delivers an effective treatment scheme for the reuse and disposal

of the produced water which in turn will benefit the oil and gas production industry in cost saving on fracturing water and the environment in minimizing pollutants discharge. Additionally, water withdrawal from natural reservoirs for hydraulic fracturing process will be alleviated if produced water can be recycled.

## 2. LITERATURE REVIEW

### 2.1. Produced water

In unconventional oil extraction, hydraulic fracturing technology has been applied to ensure high and prolonged production of gas and/or oil from shale deposits. This technology induces cracking network in low-permeability shale to allow trapped oil and/or gas flow to the production wells. To do so, hydraulic fracturing fluids are injected into to a wellbore at extremely high pressure and flow rate. Hydraulic fracturing fluid, which 98% to 99% of the total volume is water, contains a variety of additives (Table 2.1) that are added to increase the performance of the fluid and to keep the fractures remain open during the production.

**Table 2.1.** Hydraulic fracturing fluid additives

Additives	Common chemicals	Proportion (v) %	Purposes
Proppant	Sand	1-1.9*	Keeps the fractures open
Acid	HCl	0.150**	Helps dissolve minerals and initiate cracks in the rock
Scale inhibitor	Phosphate esters	0.075**	Prevent mineral scale precipitates in pipe and fractures
Thickeners	Guar gum	0.05**	Thickens the water to suspend the proppant
Biocide	GA	0.005-0.05*	Disinfect bacteria that produce corrosive by-products
Friction reducer	Polyacrylamide	0.03*	Slicks the water to minimize friction
Surfactants	Lauryl sulfate	0.0005-0.002*	Reduce surface tension of the fluid in the formation and improve fluid recovery from well
Corrosion inhibitor	Amines, amides	0.002**	Protect casing from corrosion

Source: \*King (2012); \*\*Ferrer & Thurman (2015)

About 10,000 to 30,000 m<sup>3</sup> of fracturing fluid is required for a single well injection (He et al., 2014). However, the range can vary from 4,000 to 50,000 m<sup>3</sup> per well (Cooley et al., 2012). Typically, 10% to 70% of fracturing fluid returns to the surface as flowback water within the first

few weeks after completion of hydraulic fracturing, generating a stream of wastewater that requires proper handling and treatment before being reused or discharged to the environment (Lester et al., 2013). Despite the additives found in fracturing fluids, contaminants in flowback water also come from the formation water and dissolution of shale, which are dissolved and suspended salts and metals, dissolved and non-aqueous hydrocarbons, and in some locations, naturally occurring radioactive materials (Murali Mohan et al., 2013).

Flowback and formation waters are collectively known as produced waters. The concentration of total dissolved solid (TDS) in produced water is up to 400,000 mg/L (Clark & Veil, 2009). During the fracturing process, some additives are used up in the well (strong acids, polymer precursors), while others partially react and come back gradually (surfactants, scale inhibitors, solvents, biocides) (King, 2012; Veil, 2010; Vengosh et al., 2014). Selected characteristics of flowback water from the Marcellus shale, Pennsylvania, United States, are shown in Table 2.2.

Currently, discharge of produced water into salt water wells (deep well injection) is the most common practice. However, recently there has been pressure from authorities and public that push the wastewater (produced water) producers to look for sustainable treatment solutions (Lester et al., 2013). High concentrations of TDS (up to 400 g/L) are the main obstacle for reusing it (He et al., 2014; Olsson et al., 2013). Produced water constituents that have significant impacts on the environment are TDS, chlorides, surfactants, gelling agents, metals, corrosion inhibitors, friction reducers, and biocides (PTAC, 2011). Several steps of treatment are needed before produced water can be reused or safely discharged into the environment.

**Table 2.2.** Selected chemical characteristics of flowback water sampled 5 days after hydraulic fracturing process

Parameters	Range	Median	Units
pH	5.8 – 7.2	6.6	-

## 2.2. Glutaraldehyde

### 2.2.1. Characteristics

GA (or 1,5-pentanedial) is a saturated aliphatic dialdehyde with registered CAS No. 111-30-8. GA, a colorless to a pale straw-colored oily liquid substance with a pungent odor, is an industrial biocide, used intensively for over 40 years in many industries such as health care, water treatment, pulp and paper, and oil production. In addition, it is used as a reagent for cross-linking proteins, fixing tissue samples, developing X-ray film, and immobilizing enzyme (Kawahara et al., 1992; Kist et al., 2013; Leung, 2001; Migneault et al., 2004; Russell, 1994). These extensive applications of GA are due to its broad spectrum biocidal activities and versatility on different surfaces including rubber and plastic wares, and for being non-corrosive to stainless steel, soft metal and glass (Banner, 1995; Russell, 1994).

GA is a non-oxidized antimicrobial agent; its biocidal action is depending on the cross-linking with amino groups at the microbial cell surface in such a way that cellular permeability is

altered. The ability of the cell wall to transport nutrients to cell and to remove waste products from the cell is disabled resulting in cell death (Russell & Chopra, 1996; Simons et al., 2000). It possesses a fatal biocidal activity against all types of microorganisms, bacteria, mycobacteria, spore, fungi, and viruses, and it is classified as a high-level disinfectant (Russell, 1994).

GA is stable at room temperature, pH from acidic to neutral, and to sunlight. It is mainly available in a stable state as acidic (pH 3.0–4.0) aqueous solutions, ranging in concentration from less than 2% to 70% w/v (Migneault et al., 2004). The properties of GA are shown in Table 2.3.

**Table 2.3.** Physical and chemical properties of glutaraldehyde

Molecular formula	C <sub>5</sub> H <sub>8</sub> O <sub>2</sub>
Structural formula	
Molecular weight	100.12 g/mol
Melting point	-14°C
Boiling point	188°C
Density	0.72 g/cm <sup>3</sup>
Vapor pressure	0.6 mm Hg at 25°C
Solubility	water, alcohol, benzene, ether
Water Solubility	Miscible
log <i>K</i> <sub>ow</sub>	-0.18
Henry's law constant	1.1 × 10 <sup>-7</sup> atm·m <sup>3</sup> /mol
Conversion factor	4.1 mg/m <sup>3</sup> per ppm at 25°C

Source: Emmanuel et al. (2005)

### 2.2.2. Toxicity

There is no evidence of carcinogenic activity of GA; however, it is considered a toxic compound that can be irritating and corrosive to skin, eyes and respiratory tract. It is required a well precaution protection for those who are working with the chemical (Takigawa & Endo, 2006). In the environment, GA is believed to have low adsorption on sediment and low tendency to bioaccumulate. Thus, most of the GA that is released to the environment would remain active in aquatic compartment and is an obvious threat to aquatic organisms (Emmanuel et al., 2005; Leung,

2001). GA is slightly toxic to crabs, ( $LC_{50}$  for green crab is 465 mg/L) shrimps and sewage microorganisms, and slightly to moderately toxic to fish and *Daphnia*. Algae is the most sensitive aquatic species to GA with  $LC_{50}$  less than 1 mg/L, while the median lethal concentration of GA for other aquatic organisms is around 7 mg/L (Kist et al., 2013; Leung, 2001).

### **2.3. Overview of glutaraldehyde remediation**

There is a limited number of studies on GA removal. Jordan et al. (1996) used  $NaHSO_3$  (sodium bisulfite) to chemically deactivate GA. At pH 8, GA readily reacted with  $NaHSO_3$  and complete loss of GA was observed at a ratio of  $NaHSO_3$  to GA of 2.2:1. The byproducts (GA-bisulfite complexes) had no effect on the growth of sewage microorganisms even at a concentration as high as 1 mM as GA and the acute toxicity to *Daphnia magna* was reduced by 10-fold compared to that of GA alone.

In another study, Kist et al. (2013) attempted to remove GA from hospital wastewater by UV,  $O_3$ , and UV/ $O_3$  (photoozonation). Due to its higher removal efficiency, only UV/ $O_3$  was studied in detailed. At pH 7, the removal efficiency of GA by UV/ $O_3$  from wastewater sample was 23.3% for the first 60 min, while the removal of GA in aqueous solutions was up to 72.0-75.0% for the same conditions. The low degradation for the wastewater sample was caused by reactivity between ozone and  $\bullet OH$  (from photolysis of  $O_3$ ) with other organic compounds.

### **2.4. Remediation with photolysis**

Photolysis has been used to degrade organic contaminants such as pesticides (Burrows et al., 2002) and pharmaceuticals (Lin & Reinhard, 2005; Yamamoto et al., 2009). Unlike other treatment technologies, photolysis can be used in all media – aqueous, soil and air. All of organic compounds are photodegradable but the rates differ enormously from compound to compound depending on their chemical bonds and the incident wavelength. Once organic molecules are

irradiated, bonds are rarely broken at random, instead, the excited molecules undergo fairly selective bond breaking, rearrangement or bimolecular reactions (Kagan, 1993). For reference, a 254 nm wavelength generates enough energy for homolytic cleavage of almost all chemical bonds of organic molecules (Table 2.4). In general, light containing shorter wavelengths is much more destructive than visible light.

In aqueous environment, photolysis occurs in two different mechanisms: (i) direct photolysis where the target compound absorbs light by itself, leading to bond cleavage, and (ii) indirect photolysis where a strongly absorbing molecule other than the pollutant (photosensitizer) absorbs light and initiates a series of reactions that result in the degradation of the pollutant.

**Table 2.4.** Energies and wavelengths for homolytic fission of typical chemical bonds

Bond	Energy (kcal/mol)	$\lambda$ (nm)
C=O*	178	160
C=C	160	179
C-H	95-100	286-301
O-H	85-115	249-336
C-C	85	336
C-O	80-100	249-336
C-Cl	60-86	332-477
C-Br	45-70	408-636
O-O	35	817

\*Only for carbonyl, ester, amide and halide compounds; for C=O (CO<sub>2</sub>) = 191 kcal/mol

#### 2.4.1. Direct photolysis

Direct light absorption by the target chemical will lead it to excited singlet state, which may then undergo intersystem crossing to produce triplet states. Such excited states can undergo, among other processes: (i) homolysis, (ii) heterolysis, or (iii) photoionization (Figure 2.1).

**Figure 2.1.** Possible chemical events taking place upon direct photolysis (Emília Azenha et al., 2013)

#### 2.4.2. Indirect photolysis

An important benefit of photosensitized photolysis is the possibility of using light of wavelengths longer than those corresponding to the absorption characteristic of the pollutant. The most important photosensitizers in aquatic environment are dissolved organic matter (DOM), nitrate, and nitrite. Electronically excited photosensitizers form singlet oxygen ( $^1\text{O}_2$ ),  $\bullet\text{OH}$ , DOM-derived peroxy radicals ( $\text{ROO}^\bullet$ ), triplet state DOM ( $^3\text{DOM}^*$ ), solvated electrons ( $e_{\text{aq}}^-$ ) and other photooxidants that can react with the pollutant (Emília Azenha et al., 2013; Lin & Reinhard, 2005). Following light absorption, the photosensitizer (Sens) can transfer energy from its excited state to the pollutant (Equation 2.1), which can then undergo different intermolecular reactions or intermolecular photophysical processes (Figure 2.2).

**Figure 2.2.** Chemical events taking place upon photosensitized photolysis involving energy transfer (Emília Azenha et al., 2013)

### 2.4.3. Photolysis of aldehydes

Aliphatic aldehydes are known to have absorption bands to UV light in a range of 240-360 nm (Shemesh et al., 2014). In gas state, photolysis of aldehydes undergoes the following reactions:

Reaction 2.2 is the molecular fragmentation channel, which yields hydrocarbon and carbon monoxide. Reaction 2.3, Norrish type I reaction, is the radical splitting channel. Two free radicals are formed by this process, the radicals proceed through a variety of secondary reactions to form final products. Reaction 2.4 is called Norrish type II reaction, where the byproducts are alkene and acetaldehyde. This mechanism is only possible for aldehydes larger than butanal. Reaction 2.5 is an H-abstraction process, which is minor in small aldehydes (Haas, 2004; Kagan, 1993; Shemesh et al., 2014).

In term of degradation pathways and byproducts, photolysis of aldehydes in aqueous phase is distinctly different from those in gas phase, presumably owing to the recombination of the produced radicals (Leighton, 1937). The information on photolysis of aldehydes in aqueous phase is very limited. In a study of UV-photolysis of aqueous formaldehyde conducted by Hirshberg & Farkas (1937), they found that some proportion of carboxylic acid was formed, while Pavlovskaya & Telegina (1974) observed that formyl radical ( $\bullet\text{HCO}$ ) and glyoxal (combination of two formyl radicals) were formed as the photoproducts of photolysis of aqueous formaldehyde. Hirshberg & Farkas (1937) also found that the removal efficiency of 50 mM of aqueous acetaldehyde was 70% after exposure to UV light for one hour, while the degradation rate of formaldehyde was 40 times slower than that of acetaldehyde.

#### 2.4.4. Remediation with photocatalysis

Photocatalysis is widely referred to the process of using light to activate a substrate (photocatalyst) in order to produce reactive species that could modify and/or facilitate the kinetics of a chemical reaction while the substrate itself remains unconsumed (Banerjee et al., 2014). Photocatalysis has been studied extensively for environmental remediation and energy production since Fujishima & Honda (1972) demonstrated the potential of photoelectrochemical reactivity of titanium dioxide ( $\text{TiO}_2$ ) to split water.

Figure 2.3 depicts the basic process during photocatalysis. A photocatalyst (usually a semiconductor) absorbs light, where the energy of the incident photons is equal or higher than the band gap of the semiconductor; the absorbed photon induces the excitation of an electron ( $e^-$ ) from valence band (VB) to the conduction band of the semiconductor leaving a positive electron hole ( $h^+$ ) on its VB generating high-energy charge carriers (electron-hole pair) in the semiconductor (Equation 2.6). The charge carriers separate and migrate to the surface of the semiconductor where they initiate chemical reactions.

**Figure 2.3.** Basic process of photocatalysis of a semiconductor

The photoexcited  $e^-$  can initiate electrochemical reduction, for example, reducing protons to hydrogen or reducing oxygen to superoxide radical (Equation 2.7). The photo-generated  $h^+$  can initiate electrochemical oxidation, for example, oxidizing the molecule of water or  $OH^-$  absorbed on the surface of the semiconductor to hydroxyl radical (Equation 2.8). Both electrochemical oxidation and reduction driven by charge carriers on the surface of the semiconductor generate reactive oxygen species (ROS) that can degrade organic pollutant (Equation 2.9). However, the photo-generated charge carriers also undergo recombination that releases energy in a form of heat or luminescence (Equation 2.10). This process reduces the overall efficacy of the photocatalysis.

TiO<sub>2</sub> based photocatalysts are one of the most studied photocatalysts due to their high chemical and physical stability, low toxicity, readily availability, low costs, and excellent photoactivity. Even though with these advantages, TiO<sub>2</sub>-based photocatalysts have some drawbacks that limit their uses in environmental and energy applications. The main limitations of TiO<sub>2</sub>-based photocatalysts are the rapid recombination of charge carriers resulting in quantum efficiency reduction. In addition, wide band gaps of TiO<sub>2</sub> (3.0 eV for rutile and 3.2 eV for anatase TiO<sub>2</sub>) also restrict light absorption to only ultraviolet region ( $\lambda < 400$  nm), thus limiting the application of TiO<sub>2</sub>-based photocatalysts for solar light harvesting.

In recent years, there has been a particular interest in the development of visible light photocatalysts that can be used to harvest solar energy. Visible light photocatalysis has been considered as one of the most effective strategies to tackle the challenging problems the world

facing such as energy shortage, environmental pollution and global warming (Jing et al., 2013; Moniz et al., 2015; Wang et al., 2014).

In environmental applications, visible light photocatalysts have been synthesized and examined their performances on various hazardous pollutants including organic compounds, heavy metals, and pathogens. In a study by Choi et al. (2014), the removal of four pharmaceuticals (Acetaminophen, carbamazepine, cimetidine and propranolol) using Pt doped  $\text{WO}_3$  as a photocatalyst under visible light ( $\lambda > 400 \text{ nm}$ ) has been investigated. At the concentration of 0.5 g/L of photocatalyst and pH 8.0, all four pharmaceuticals ( $1 \mu\text{M}$ ) were completely removed within 60 min of irradiation in distilled water. However, when tested in secondary effluent from wastewater treatment plant, removal kinetics drastically reduced due to the presence of organic compounds as  $\bullet\text{OH}$  scavenger in the effluent.

Photocatalysis was applied to reduce toxic and carcinogenic Cr(VI) to Cr(III), which is 100 times less toxic (Wang et al., 2016).  $\text{AgI/BiOI-Bi}_2\text{O}_3$  was used at a concentration of 1 g/L to remove 4 mg/L of Cr(VI) in deionized (DI) water at unadjusted pH of 6.08. More than 90% of Cr(VI) was reduced within 90 min irradiation under visible light ( $\lambda > 420 \text{ nm}$ ) with a first order rate constant of  $0.032 \text{ min}^{-1}$ . Another application of photocatalysis is for water disinfection. Liu et al. (2016) successfully synthesized highly reactive vertically aligned  $\text{MoS}_2$  to inactivate *E. coli* in DI water. With a small concentration (1.6 mg/L) of the photocatalyst, more than 99.999% of the bacteria were inactivated within 60 min irradiation under natural sunlight.

### **3. UV PHOTOLYSIS OF GLUTARALDEHYDE IN PRODUCED WATER**

#### **3.1. Introduction**

In unconventional oil and gas extraction, hydraulic fracturing technology has been applied to ensure high and prolonged production of oil and gas from shale deposits. This technology induces cracking network in low-permeability shale to allow trapped oil and/or gas flow to the production wells by injection of hydraulic fracturing fluid at an extremely high pressure and flow rate. Hydraulic fracturing fluid, of which 98% to 99% of the total volume is water, contains a variety of additives. Typically, hydraulic fracturing requires water ranging from 10,000 to 30,000 m<sup>3</sup> per well (He et al., 2014); however, the range can vary from 4,000 to 50,000 m<sup>3</sup> per well (Cooley et al., 2012). In the first 30 days after the fracturing process is completed, about 10-70% of injected fracturing water returns to the surface, known as flowback water (American Petroleum Institute, 2010). The water that flows to the surface, flowback water and/or formation water (naturally occurring water in shale) until the end of the life of a well, is called produced water. In addition to the additives found in fracturing fluids, contaminants in produced water also come from dissolution of shale, which among other chemicals/minerals contains dissolved and suspended salts and metals, dissolved and non-aqueous hydrocarbons, and in some locations, naturally occurring radioactive materials (Murali Mohan et al., 2013). This water tends to have high contents of minerals and hydrocarbons.

Produced water (oil and gas production wastewater) contains various chemicals that cause significant environmental concerns. Discharging produced water into deep salt water wells is the most common practice; however, recently pressure from authorities and public is pushing the wastewater producers to look for sustainable treatment solutions (Lester et al., 2013). Currently,

in Pennsylvania, almost all of the produced water is treated and eventually the treatment could be required nationwide (Rozell & Reaven, 2012).

Biocides are considered one of the most harmful contaminants in produced water (King, 2012; Rimassa et al., 2011). GA, the most common biocide used in hydraulic fracturing fluid, accounts for 80% of all shale fracturing (King, 2012). It is also used periodically to keep the number of bacterial cells low in the production well (Fakhru'l-Razi et al., 2009). GA is classified as a high-level disinfectant due to its lethal action against all types of microorganisms (Russell, 1994). Since it is used extensively by the oil and gas industry, it is very likely that large amounts of produced waters containing GA are being generated (Vengosh et al., 2014). The presence of GA in polymeric forms has been reported in produced water in Colorado (Ferrer & Thurman, 2015). In the environment, GA is very toxic to aquatic organisms, especially algae, microorganisms, and freshwater fishes (Leung, 2001).

In addition to its toxicity, the other obvious issue with GA in produced water is the restriction of biological activities making biological treatment a non-viable alternative for them. In a study of biodegradability of tanning agents, GA at a concentration of 2.5 mg/L inhibited activated sludge process (Sun et al., 2008). Biological treatment (Bioremediation) is the most preferred treatment technology since it is economical and effective against a variety of environmentally harmful chemicals including those in produced water such as gelling agents, surfactants, and organic materials. However, GA limits the application of biological treatment. Thus, removing GA from produced water would be beneficial for both the environment and wastewater recyclability and disposal.

There is a limited number of studies on GA removal. Jordan et al. (1996) used  $\text{NaHSO}_3$  (sodium bisulfite) to chemically deactivate GA (Jordan et al., 1996). At pH 8, GA readily reacted

with  $\text{NaHSO}_3$  and complete loss of GA was observed at a ratio of  $\text{NaHSO}_3$  to GA of 2.2:1. Kist et al. (2013) attempted to remove GA from hospital wastewater by UV,  $\text{O}_3$ , and UV/ $\text{O}_3$  (photoozonation) (Kist et al., 2013). Due to its higher removal efficiency, only UV/ $\text{O}_3$  was studied in detailed. At pH 7, the removal efficiency of GA by UV/ $\text{O}_3$  from wastewater sample was 23.3% for the first 60 min, while the removal of GA in aqueous solutions was up to 72.0-75.0% for the same conditions. The low degradation for the wastewater sample was caused by reactivity between ozone and  $\bullet\text{OH}$  (from photolysis of  $\text{O}_3$ ) with other organic compounds. To the best of knowledge, there is no previous study on photolysis of GA in brine and the photolytic mechanisms and pathway of GA.

This research focused on photolysis of GA in brine solutions simulating pretreated produced waters since this technology has small footprints and is easy to operate. The objectives of the research are (1) to examine the optimal operating conditions such as light intensity and pH for GA photolysis, and (2) to identify the photolytic byproducts of GA and elucidate degradation mechanisms and pathways. Batch experiments of photolysis of GA in synthetic produced water were conducted using a photochamber equipped with UV lamps with primary illumination at 254 nm.

## **3.2. Methodology**

### **3.2.1. Materials**

GA, Grade II in a 25% (w/v) aqueous solution was obtained from Sigma-Aldrich (St Louis, MO, USA). A derivatizing reagent O-(2,3,4,5,6-pentafluorobenzyl)-hydroxylamine-HCl (PFBHA), 99%+ was obtained from Alfa Aesar (Ward Hill, MA, USA). GA and PFBHA were used as received. Analytical grade hexane was purchased from VWR (Radnor, PA, USA). Sodium chloride was purchased from Merck (Darmstadt, Germany) and was baked overnight at 450°C

before use. Reverse osmosis DI water was used throughout this research. All other reagents that were used are of analytical-reagent grade.

### **3.2.2. Sample preparation**

A stock solution containing 100 mM of GA was prepared by diluting a 25% solution of GA in DI water and stored at 4°C. Synthetic samples were prepared by diluting the stock solution with DI water to obtain desired GA concentrations. NaCl was added to the sample to simulate produced water. Na<sup>+</sup> and Cl<sup>-</sup> are the most dominant constituents and contribute to the majority of total dissolved solids up to 400 g/L in produced water (Clark & Veil, 2009). pH of the synthetic samples was buffered by 10 mM phosphate. pH was adjusted to the final point by either 1 M NaOH or 1 M HCl.

Most experiments were conducted under the following conditions: GA of 0.1 mM, NaCl of 200 g/L, and pH 7. The initial GA concentration of 0.1 mM was chosen based on the potential toxicity and biocidal activities. This level of GA inhibits microbial activities (UCC, 1994) and therefore would prohibit the applicability of biological processes for produced water treatment. Moreover, in case of leakage, GA may remain in receiving water to pose an adverse effect on aquatic organisms. For example, its lethal concentration (LC<sub>50</sub>) for algae is less than 0.01 mM (Leung, 2001). The values of NaCl and pH used, are commonly reported in actual produced water (Benko & Drewes, 2008; Clark & Veil, 2009; Gregory et al., 2011). To examine the effects of initial GA concentration, salt concentration, and pH on photolysis performance, the following conditions were experimented: GA concentrations of 0.1, 0.5 and 1 mM; NaCl concentrations of 0, 50, 100, 200 and 300 g/L; and pH 5, 7, and 9. For GA degradation mechanism investigation, isopropyl alcohol (IPA) was added to the sample at 1% (v/v) to quench •OH whereas NaN<sub>3</sub> was added to the sample at 10 mM to quench <sup>1</sup>O<sub>2</sub>. The synthetic samples were prepared fresh daily.

### 3.2.3. Photoreaction

Photodegradation was conducted in a Rayonet RPR-200 photochamber. The chamber was able to accommodate up to 16 lamps (RPR-2537A). Most of the experiments were conducted with 16 lamps (14 W each) with primary illumination at 254 nm. The effect of light intensity was experimented by controlling the number of lamps installed in the chamber (8, 12 and 16). Photon irradiance at different light intensities was measured by actinometry (for details see subsection 3.2.7). One to six cylindrical quartz test tubes (35-mL, Quartz Scientific, Fairport, OH) holding about 25 mL of sample per tube were placed vertically on a merry-go-round, which rotated at 5 rpm in the middle of the reactor. Irradiation was conducted for 60 min with 2-mL sampling for every 10 min using a pipettor. The temperature in the chamber during the experiment was controlled below 40°C during operation by a cooling fan under the chamber. Each photolytic experiment was carried out in triplicate.

### 3.2.4. GA quantification

GA was derivatized with PFBHA, which reacts with the carbonyl groups of GA to form GA-oxime. The derivative procedure is as follows. In a 5-mL polypropylene tube (Eppendorf, Germany), 2 mL of sample and 0.1 mL of aqueous PFBHA (10 g/L) were placed, mixed and kept in the dark at room temperature for 1 h. After that, 20  $\mu$ L of 9 M sulfuric acid was added to the mixture followed by 1 mL of hexane containing 1 mg/L of 1,3-dibromopropane, as an internal standard to extract GA-oxime. The mixture was shaken vigorously by hand for 3 minutes and left idle for separation by gravity for another one minute. Finally, the hexane layer was transferred to a 2-mL vial for analysis.

The extract was analyzed by a gas chromatograph-flame ionization detector (GC-FID). A Varian GC-FID (Varian 3900) equipped with HP-5ms, capillary column, (30 m  $\times$  0.25 mm with

0.25  $\mu\text{m}$  film thickness) was used. The operating conditions for the GC-FID were as follows: injection volume of 1  $\mu\text{L}$ , He carrier gas constant flow at 1.5 mL/min, injection temperature at 250°C, splitless injection mode with split valve open at 1 min, split flow at 45 mL/min, column temperature at 50°C for 1 min, then ramping at 4°C/min to 70°C, then at 10°C/min to 210°C, then at 4°C/min to 220°C, then at 40°C/min to 260°C with a 3-min final hold. The total run time was 26.50 min.

The instrument was calibrated daily with five-point calibration (0.001 to 0.1 mM). Standard solutions were prepared fresh from a stock solution in DI water. A calibration curve was constructed based on Equation 3.1 (See Appendix Table A.1 for GC peak area of GA and internal standard; and Appendix Figure A.1 for the calibration curve).

$$\text{RF} = \frac{A_{\text{GA}}/A_{\text{IS}}}{C_{\text{GA}}/C_{\text{IS}}} \quad (\text{Equation 3.1})$$

Where: RF = response factor (slope of the calibration curve)  
 $C_{\text{GA}}$  = concentration of GA  
 $C_{\text{IS}}$  = concentration of internal standard (1,3-dibromopropane)  
 $A_{\text{GA}}$  = peak area of GA  
 $A_{\text{IS}}$  = peak area of internal standard

### 3.2.5. Total organic carbon

Total organic carbon (TOC) was measured using a UV/persulfate oxidation TOC analyzer (Phoenix 8000, Tekmar Dohrmann, OH, USA). To overcome the interference from  $\text{Cl}^-$ , samples with an initial NaCl concentration of 200 g/L were diluted 10 times with DI water and 40% (w/v) sodium persulfate solution was used to analyze the diluted samples (instead of no dilution and 10% (w/v) sodium persulfate solution for samples with no or low salt).

### 3.2.6. Photoproduct analysis

For photoproduct identification, a higher GA concentration at 0.2 mM in DI water was used in the photolysis experiment in order to be able to detect minor photoproducts. The sample

was irradiated for 2 h with 224 W of light intensity (16 lamps  $\times$  14 W). Photoproducts were determined by the high resolution mass spectrometric (HR-MS) method. Mass spectra of unirradiated and irradiated samples were obtained from Synapt G2-Si HDMS with ToF ESI positive mode (Waters, Corporation, Inc). In this method,  $^{23}\text{Na}^+$  was used as the primary adduct for ionization process. Sample was directly infused into the mass spectrometer (MS) at a flow rate of 10  $\mu\text{L}/\text{min}$ . Before analysis, the instrument was properly calibrated using sodium formate as a standard. All  $m/z$  values used were within the 5 ppm difference compared to the theoretical masses.

### 3.2.7. Quantum yield

Quantum yield was determined by mean of ferrioxalate actinometer (Bolton et al., 2011). A ferrioxalate solution for photolytic experiment at 6 mM in 0.1 N  $\text{H}_2\text{SO}_4$  was prepared as follows. In a 250-mL volumetric flask containing 150 mL DI water, 0.7 mL concentrated  $\text{H}_2\text{SO}_4$  was added slowly followed by 840 mg of  $\text{K}_2\text{C}_2\text{O}_4 \cdot \text{H}_2\text{O}$  and 784.3 mg of  $\text{Fe}_2(\text{SO}_4)_3$  hydrates ( $\text{Fe}^{3+}$  was at 21.3% determined by UV absorption at 302 nm). The solution was stirred until all the solids dissolved and finally DI water was added to the volume (250 mL). Laboratory lighting was turned off during the preparation of ferrioxalate solution to minimize photolysis of ferrioxalate.

Photolytic reaction of ferrioxalate solution was performed exactly the same as those of GA photolytic experiments. Briefly, a 25-mL of ferrioxalate solution in a quartz test tube was placed in the merry-go-round in the photochamber and the reaction was conducted for 60 s. Different light intensities were used, 224, 168 and 112W (16, 12 and 8 lamps). The photoreaction experiment was triplicated for each light intensity.

At the end of the photoreaction, 0.5 mL ( $V_1$ ) of the irradiated sample was added to a 10-mL ( $V_2$ ) volumetric flask containing 1 mL of 0.1% (w/v) 1,10 phenanthroline and 1 mL of 0.6 M sodium acetate buffer. DI water was added to the final volume (10 mL). The mixture was left for

1 h. The complexation between  $\text{Fe}^{2+}$  and 1,10 phenanthroline was formed which was then determined based on absorbance at 510 nm. Formed  $\text{Fe}^{2+}$  was determined by the following equation:

$$\text{moles Fe}^{2+} = \frac{(A_{\text{irradiated sample}} - A_{\text{unirradiated sample}}) \times V_2 \times V}{\epsilon_{\text{Fe}^{2+}\text{-o-phenanthroline}} \times 1,000 \times V_1} \quad (\text{Equation 3.2})$$

Where: A = absorbance;  $V_1$  = volume of irradiated sample used in complexation (0.5 mL);  $V_2$  = volume of final complexation solution (10 mL); V = volume of irradiated sample (25 mL); and  $\epsilon$  = extinction coefficient of  $\text{Fe}^{2+}$ -o-phenanthroline complex ( $11,100 \text{ M}^{-1} \text{ cm}^{-1}$ ). See Appendix Table A.2 for the absorbance and Appendix Figure A.2 for UV-Vis absorbance spectra of unirradiated and irradiated samples at different light intensities.

Photon irradiance,  $E_p$ , ( $\text{einstein cm}^{-2} \text{ min}^{-1}$ ) was determined by the following equation:

$$E_p = \frac{\text{moles Fe}^{2+}}{\Phi_{\text{Fe}^{2+}} \times \text{Area} \times t} \quad (\text{Equation 3.3})$$

Where:  $\Phi_{\text{Fe}(2+)}$  = 1.25 ( $\text{mole einstein}^{-1}$ ) at 254 nm; Area = cross sectional area of the test tube ( $r = 0.9 \text{ cm}$ , area =  $2.54 \text{ cm}^2$ ); and  $t$  = irradiated time (1 min).

Finally, the quantum yield of GA was determined by the following equation (Zepp, 1978):

$$\Phi = \frac{k_{obs}}{2.303 E_p \times \epsilon_{254}} \quad (\text{Equation 3.4})$$

Where:  $\Phi$  = quantum yield of GA ( $\text{mole einstein}^{-1}$ );  $k_{obs}$  = GA photolysis rate constant ( $\text{min}^{-1}$ );  $E_p$  = photon irradiance ( $\text{einstein cm}^{-2} \text{ min}^{-1}$ ) obtained from the above ferrioxalate actinometric method, and  $\epsilon_{254}$  = extinction coefficient of GA at 254 nm ( $\text{cm}^2 \text{ mole}^{-1}$ ). See Appendix Table A.3 for the absorbance of GA at different concentrations at 254 nm and the calculation of  $\epsilon_{254}$ .

### 3.2.8. Statistical analysis

One-way analysis of variance (ANOVA) test was performed using Minitab software (version 18.1, 2017) with the posthoc Tukey Test to compare the kinetics of GA removal within each treatment (light intensity, pH, initial GA concentration, salt concentration, and quenchers).

The significance criterion ( $\alpha$ ) is 0.05. The detailed results of ANOVA and Tukey Test are provided in Appendix, Tables A.4-A.9.

### **3.3. Results and discussion**

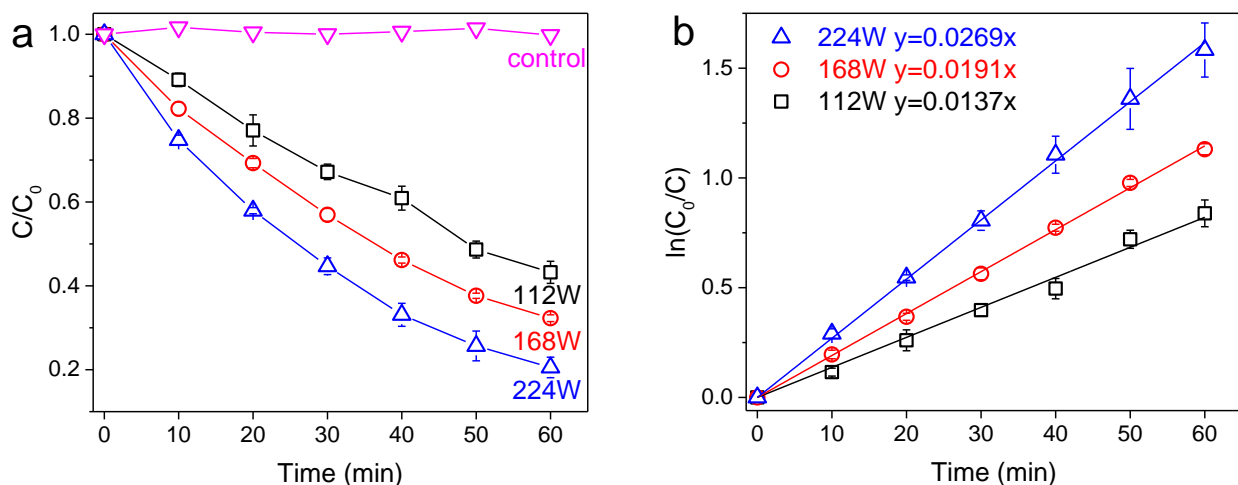

#### **3.3.1. Effect of light intensity**

After 60 min of irradiation, GA removal by 112, 168 and 224 W (featuring 8, 12, 16 lamps of 14 W each) was 57%, 68%, and 80%, respectively suggesting that GA can be photolyzed by UV irradiation (Figure 3.1a). For a control, where the sample was kept in the dark, there was no reduction of GA over the course of 60 min, suggesting that photolysis was responsible for GA degradation. The kinetic modeling is depicted in Figure 3.1b. It shows that GA photolysis fits well ( $R^2 > 0.99$ ) with pseudo-first order reaction whereas other models (zero and second order) did not show any good regression results. Photolysis of GA significantly increased with the increasing light intensity. GA decomposition rate constant ( $k_{obs}$ ,  $\text{min}^{-1}$ ) increased about two folds from 0.0137 to  $0.0269 \text{ min}^{-1}$  with a two-fold increase in light intensity 112 to 224 W, again showcasing that the removal was from light illumination and not due to a dark reaction. Table 3.1 displays the quantum yields of GA at different light intensities. The quantum yields of GA at the two higher light intensities, were the same while it increased about 20% at the lowest light intensity (112 W). However, ANOVA test results show that there are no significant differences of quantum yields among the three light intensities. In this research, the highest light intensity at 224 W, which provided the best removal efficiency (80%), was used in later experiments.

#### **3.3.2. Effect of pH**

The effect of pH on GA photolysis (224 W) was studied at pH 5, 7 and 9 using 10 mM phosphate as a buffer. The result indicates that there was an increase of the photodegradation rate constant with decreasing pH. At pH 5, the removal rate was  $0.0309 \text{ min}^{-1}$  which was insignificantly

higher than  $0.0269 \text{ min}^{-1}$  at pH 7 but significantly higher than  $0.0247 \text{ min}^{-1}$  at pH 9 (Figure 3.2). A similar result was reported by Kist et al. (2013) that researched on GA removal using  $\text{O}_3/\text{UV}$ ,  $\text{O}_3$  and UV. They found that under alkaline condition, the efficiency of photolysis of GA under UV was the lowest compared to neutral and acidic conditions. This could be because under alkaline conditions, the enol form of GA might play a role in the degradation compared to the keto form that is likely protonated in strongly acidic conditions. Although pH 5 gave a better performance of GA photolysis, pH 7 was selected for all other experiments because it is the pH commonly reported for produced water (Benko & Drewes, 2008; Clark & Veil, 2009; Gregory et al., 2011).

**Figure 3.1.** Effect of light intensity on GA photolysis (a) removal efficiency and (b) removal rate constant ( $[\text{GA}]_0 = 0.1 \text{ mM}$ ,  $\text{NaCl} = 200 \text{ g/L}$ ,  $\text{pH} = 7$ )

Note: Corresponding GA concentrations can be found in Appendix Table A.10

**Table 3.1.** Quantum yield of GA at different light intensity

Light power	$k_{\text{obs}}$ ( $\text{min}^{-1}$ )	$\varepsilon$ ( $\text{cm}^2 \text{ mole}^{-1}$ )	$E_p$ (einstein $\text{cm}^{-2} \text{ min}^{-1}$ )	$\Phi$ (mole einstein $^{-1}$ )
224 W	0.0269	22702	$9.3548 \times 10^{-6}$	0.0549
168 W	0.0191	22702	$6.7001 \times 10^{-6}$	0.0545
112 W	0.0137	22702	$3.9812 \times 10^{-6}$	0.0658

### 3.3.3. Effect of GA initial concentration

Figure 3.3 shows the effect of initial concentration on GA photolysis rate. The photolysis rate constant of GA significantly decreased with increasing initial concentration. About 55% reduction of degradation rate of GA was recorded for a 10-fold increase in initial concentration of GA from 0.1 mM ( $k_{obs} = 0.0269 \text{ min}^{-1}$ ) to 1 mM ( $k_{obs} = 0.0118 \text{ min}^{-1}$ ). This type of observation has been frequently reported in literature on the photodegradation of organic compounds and was explained by the limit of photon absorption with high concentrations of reactants (Jiao et al., 2008; Prados-Joya et al., 2011).

**Figure 3.2.** Effect of pH on GA photolysis rate ( $[GA]_0 = 0.1 \text{ mM}$ ,  $\text{NaCl} = 200 \text{ g/L}$ , light intensity = 224 W)

Note: Corresponding GA concentrations can be found in Appendix Table A.11

### 3.3.4. Effect of salt concentration

The level of salt in produced waters varies greatly with the shale formation and location. It is, therefore, important to investigate the effect of salt concentration on GA photolysis. The result of this research demonstrated that different salt concentrations affected GA degradation rate. At lower salt concentrations, notable retardation of GA degradation rate was observed. As depicted in Figure 3.4 (plots of removal efficiency and rate are shown in Figure 3.5), at 0 g/L of NaCl (no

salt), the photodegradation rate was  $0.0247 \text{ min}^{-1}$ . At 50 g/L of NaCl, the rate significantly dropped to  $0.0161 \text{ min}^{-1}$  but significantly increased to  $0.0269 \text{ min}^{-1}$  at 200 g/L and to  $0.0281 \text{ min}^{-1}$  at 300 g/L of NaCl. It should be noted that the photodegradation rate was better at the two high salt concentrations, with a significantly higher rate at 300 g/L, compared to the no salt case. These trends on photodegradation rate suggest that at low and high salt concentrations different photolysis mechanisms are likely (see subsection 3.3.5).

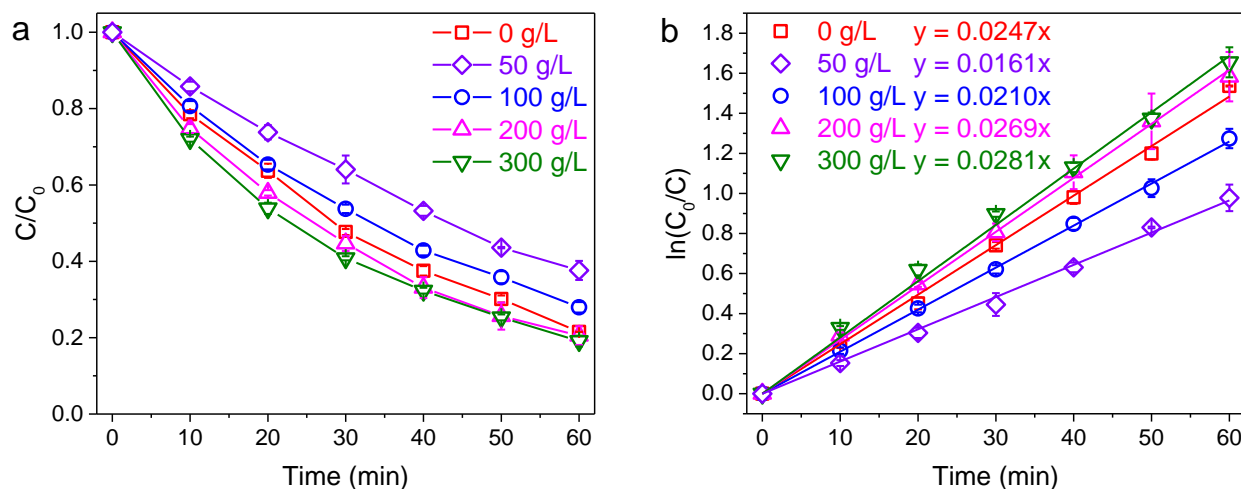

**Figure 3.3.** Effect of initial concentration on GA photolysis rate (pH = 7, NaCl = 200 g/L, light intensity = 224 W)

Note: Corresponding GA concentrations can be found in Appendix Table A.12

**Figure 3.4.** Effect of NaCl on the GA photolysis rate ( $[GA]_0 = 0.1 \text{ mM}$ , pH = 7, light intensity = 224 W)

**Figure 3.5.** Effect of concentration of NaCl on GA removal (a) efficiency and (b) rate ( $[GA]_0 = 0.1$  mM, pH = 7, and light intensity = 224 W)

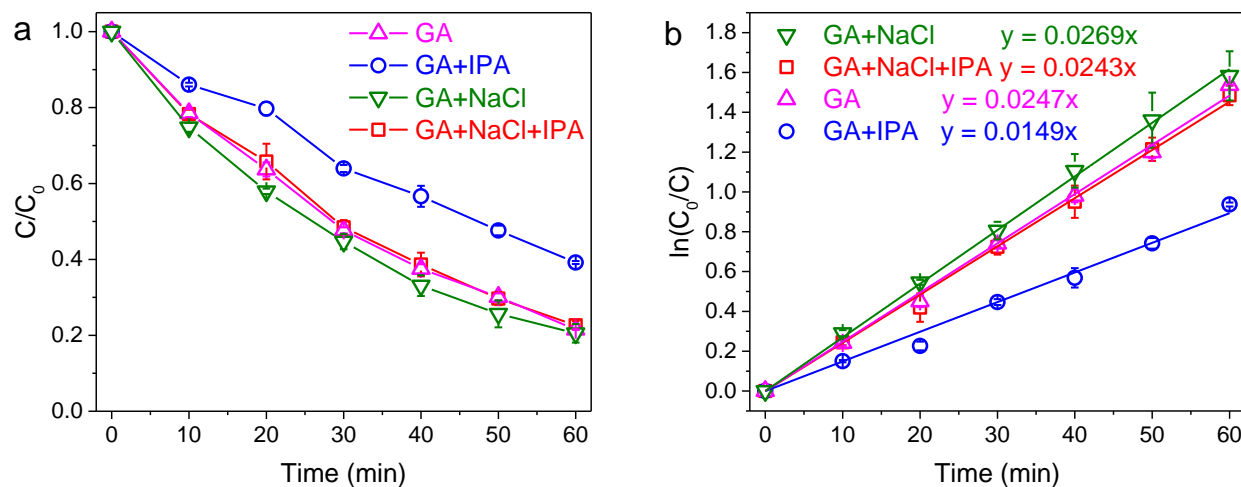

Note: Corresponding GA concentrations can be found in Appendix Table A.13

### 3.3.5. Photolytic mechanisms

Figure 3.6 depicts the results of the quenching experiment (plots of removal efficiency and rate are depicted in Figure 3.7). When IPA, as an  $\bullet OH$  scavenger, was added at 1% (v/v) to the sample, about 40% reduction in degradation rate of GA ( $k_{obs}$  decreased from 0.025 to 0.015  $\text{min}^{-1}$ ), which is significant, was observed in the sample without salt compared to insignificant 11% reduction ( $k_{obs}$  decreased from 0.027 to 0.024  $\text{min}^{-1}$ ) with salt at 200 g/L. Although indirect photolysis of GA via  $\bullet OH$  photooxidation in saline sample was much less compared to sample without salt, the total removal rate constant for saline sample was higher than that of sample without salt (0.027  $\text{min}^{-1}$  versus 0.025  $\text{min}^{-1}$ ). As mentioned above, other mechanisms may govern the photodegradation of GA in the presence of salt rather than  $\bullet OH$ . Significant reduction in GA photolysis at low salt concentrations was due to quenching of  $\bullet OH$  by  $Cl^-$ . However, as the concentration of salt (e.g. NaCl) increased, the ratio of hydrate (monomeric and oligomeric) and aldehyde GA decreased (Gruen & McTigue, 1963; Pocker & Dickerson, 1969). The increase in aldehyde GA and decrease in hydrate GA could accelerate the photolytic process.

**Figure 3.6.** Effect of IPA (1% v/v) and NaCl (200 g/L) on the GA photolysis rate ( $[GA]_0 = 0.1$  mM, pH = 7, light intensity = 224 W)

**Figure 3.7.** Effect of IPA (1% v/v) on GA removal (a) efficiency and (b) rate ( $[GA]_0 = 0.1$  mM, pH = 7, light intensity = 224 W, and NaCl = 200 g/L)

Note: Corresponding GA concentrations can be found in Appendix Table A.14

### 3.3.6. Photoproducts and photolytic pathways

TOC removal was quite low over the course of photolysis, especially in saline sample (Figure 3.8). This observation suggests that complete mineralization was not the main route of GA photolysis and therefore, the majority of organic carbon remained in the solution.

**Figure 3.8.** Total organic carbon removal of GA in pure DI water and saline sample (NaCl = 200 g/L) after 1 h irradiation ( $[GA]_0 = 0.1$  mM, pH = 7, and light intensity = 224 W)  
 Note: Corresponding TOC concentrations can be found in Appendix Table A.15

Figure 3.9 summarizes the aqueous chemistry of GA. Aqueous GA primarily consists of hydrates, cyclic hemiacetal and its oligomers (Kawahara et al., 1992; Migneault et al., 2004; Whipple & Ruta, 1974). However, Korn et al. (1972) argued that an aqueous solution of 70% GA was primarily composed of structures depicted in Figure 3.9I (15%), Figure 3.9IV and Figure 3.9V (85% for both). Their suggestion agrees with the obtained mass spectrum of GA from HR-MS in this research (Figure 3.10a), which show that structures depicted in Figure 3.9V ( $n = 2$  and 3) and Figure 3.9I were the most predominant species with little amounts of the other structures. It should be noted that peaks at  $m/z \sim 223$   $[2GA+Na]^+$  and  $\sim 323$   $[3GA+Na]^+$  were all assigned the free aldehyde form of GA (Figure 3.9I), as it is common for some analytes to have multiple molecules adducted to  $Na^+$ .

**Figure 3.9.** Structure of Aqueous GA

Figure 3.10b depicts the mass spectrum of the irradiated sample which contains more than 1,300 peaks. For  $150 < m/z < 500$ , the peak clusters were separated by a repetitive group with  $m/z \sim 14$ . In addition, peaks in this region also exhibited a regular mass difference of  $m/z \sim 14$ , 16 and 18 (equivalent to the exact mass of  $\text{CH}_2$ , O and  $\text{H}_2\text{O}$ , respectively), suggesting evidence of oligomerization (Kalberer et al., 2004). The oligomerization of GA during photolysis could be from the reaction of the free aldehyde (Figure 3.9I) and the oligomeric hemiacetals (Figure 3.9V) to form irreversible oligomers. Based on the spectrum in Figure 3.10b, this postulation is reasonable due to the majority of the most intense peaks were centralized at  $m/z$  200-300 which corresponded to the dimeric and trimeric photoproducts where dimer and trimer were also the main precursors detected. Similar findings were reported by studies of secondary organic aerosols components as the photoproducts of aldehydes and other organics in cloud droplet (Bateman et al., 2011; Guzmán et al., 2006; Kalberer et al., 2004; Loeffler et al., 2006; Reinhardt et al., 2007; Renard et al., 2014; Tolocka et al., 2004; Walser et al., 2008).

Since the method of GA quantification was also able to detect small carbonyl compounds, trace amounts of formaldehyde, acetaldehyde, acrolein and glyoxal were observed in the

chromatogram along with GA during photolysis. Even though they were detected as minor photoproducts, these small aldehydes showcase the mechanistic pathways for GA degradation under UV illumination.

**Figure 3.10.** ESI positive mode mass spectra of GA (a) before and (b) after irradiation. Initial GA concentration at 0.2 mM in pure DI water was irradiated using 224 W light intensity for 2 h. About 95% of GA were removed after irradiation.

Note: Corresponding data of GA mass spectra can be found in Appendix Table A.16-A.17

The proposed photolytic pathway of GA is presented in Figure 3.11. The primary pathway followed the photolysis of the free aldehyde form of GA to form free radicals and smaller aldehydes. The radical pathway, formation of radicals and their subsequent reactions, was responsible for the photodegradation of GA. Based on the established photochemistry of aldehydes (Turro, 1991) that originates from  $n\pi^*$  excited state. Excited GA can undergo Norrish type I and Type II reactions (Haas, 2004; Kagan, 1993). Norrish type I cleavage gave formyl radical as one the products. Formyl radical could undergo H-abstraction from the surrounding compounds to give

formaldehyde, or simply combine with another formyl radical to give glyoxal (Pavlovskaya & Telegina, 1974). In Norrish Type II, GA dissociated at beta carbon to give two free radicals which disproportionated to acrolein and acetaldehyde (Paulson et al., 2006). The Norrish Yang cyclization pathway could also lead to the formation of acrolein. Provided the unstable nature of radicals and relatively slow dehydration of GA, the formed radicals were expected to react with all forms of hydrated GA as a secondary reaction. This reaction would induce oligomerization resulting in oligomers as the final products.

**Figure 3.11.** Proposed GA photolysis pathways (with detected photoproducts are in bold)

### 3.4. Summary

GA can be photolyzed by UV at all studied conditions with the removal ranging from 52 to 85% within one hour irradiation. Photolysis of GA followed pseudo-first order kinetics. The degradation rate of GA was substantially affected by light intensity (112-224 W), initial GA concentration (0.1-1 mM) and salt concentrations (0-300 g/L) but minimally influenced by pH (5-9). Photolysis rate constant of GA at 0.1 mM in 200 g/L of salt at pH 7 was  $0.0269 \text{ min}^{-1}$  with a quantum yield of 0.0549 under 224 W illumination. The degradation rate of GA increased with increasing incident light intensity and decreasing pH. Increasing in initial GA concentration resulted in decreasing degradation rate of GA. At lower salt concentrations, notable retardation of GA degradation rate was observed. Quenching experiments were also conducted;  $\bullet\text{OH}$  was more dominant in no salt sample as compared to 200 g/L of salt. Oligomers were identified as the main photolytic byproducts and GA photolytic pathways were proposed. The findings in this research indicate that photolysis is a promising technology in removing GA in flowback and produced waters. GA removal at high salt concentrations, similar to the levels found in produced water, was better than those at zero and low salt concentrations.

## 4. PHOTOCATALYSIS OF GLUTARALDEHYDE IN PRODUCED WATER

### 4.1. Introduction

Chapter 3 describes research on the application of photolysis to degrade GA in brine solutions simulating produced waters under 254 nm UV. GA removal ranging from 52 to 85% could be achieved within one hour of irradiation under the studied conditions such as light intensity (112-224 W), pH (5-9), initial GA concentration (0.1-1 mM) and salt concentration (0-300 g/L). Recently, visible light photocatalysis has drawn considerable interests. The technology has been exploited to harvest natural sunlight for environmental remediation as well as energy production.

Most research in visible light photocatalysis has mainly focused on the fabrication of new photocatalysts. For example,  $\text{Ag}_3\text{PO}_4$ -based photocatalysts had high reactivity toward dye (Yi et al., 2010); however, these photocatalysts are not suitable for a system where  $\text{Cl}^-$  concentration is high due to the reaction of  $\text{Ag}_3\text{PO}_4$  with  $\text{Cl}^-$  to form  $\text{AgCl}$ . Other recently synthesized photocatalysts,  $\text{AgCl}$ ,  $\text{Ag}/\text{AgCl}$ , and  $\text{BiOCl}$  were studied due to their relatively high reactivity and stability. Although,  $\text{AgCl}$ ,  $\text{Ag}/\text{AgCl}$  (composite of  $\text{Ag}$  and  $\text{AgCl}$ ),  $\text{BiOCl}$  are photocatalytically active under visible light, all of them were proven to be less effective than  $\text{Ag}/\text{AgCl}/\text{BiOCl}$  composite (Xiong et al., 2011; Ye et al., 2012). As previous studies found that flower-like  $\text{BiOCl}$  had better performance compared to its flake sheet counterpart (Chen et al., 2013; Chen et al., 2012; Cheng et al., 2013), the performance of the composite photocatalyst can be improved by using flower-like  $\text{BiOCl}$ . As chloridated compounds,  $\text{AgCl}$  and  $\text{BiOCl}$  would be chemically inert to  $\text{Cl}^-$  making  $\text{Ag}/\text{AgCl}/\text{BiOCl}$  suitable for use in produced water where  $\text{Cl}^-$  is the predominant anions found.

In this research,  $\text{Ag}/\text{AgCl}/\text{BiOCl}$  photocatalyst was synthesized based on flower-like  $\text{BiOCl}$  and tested for the photocatalytic degradation of GA in brine solutions simulating produced

waters. The objectives of the research were (1) to examine the effects of operating conditions such as photocatalyst loading, pH, level of NaCl and initial GA concentration on GA photocatalysis under visible light, (2) to test the performance of GA photocatalysis under UV and natural sunlight irradiations and (3) to identify the photocatalytic mechanisms.

## **4.2. Methodology**

### **4.2.1. Materials**

Glutaraldehyde, Grade II in a 25% (w/v) aqueous solution,  $\text{Bi}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}$ ,  $\text{AgNO}_3$ , cetyltrimethylammonium chloride (CTAC), 1,4-benzoquinone (BQ), triethanolamine (TEOA), were obtained from Sigma-Aldrich (St Louis, MO, USA). A derivatizing reagent PFBHA, 99%+ was obtained from Alfa Aesar (Ward Hill, MA, USA). GA and PFBHA were used as received without further purification. Analytical grade hexane and IPA were purchased from VWR (Radnor, PA, USA). Sodium chloride was purchased from Merck (Darmstadt, Germany) and was baked overnight at  $450^\circ\text{C}$  before use. Reverse osmosis DI water was used throughout the research. All other reagents were of analytical grade.

### **4.2.2. Ag/AgCl/BiOCl synthesis and characterization**

The preparation procedure for Ag/AgCl/BiOCl photocatalyst is as follows. A solution of CTAC was prepared beforehand by dissolving 3.2 g of CTAC in 15 mL of DI water. In a 125-mL flask, 30 mL of DI water, 15 mL of glacial acetic acid and 4.85 g of  $\text{Bi}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}$  were placed and stirred until the solution became transparent. The solution was then quickly added to the CTAC solution to form microsphere BiOCl particles (Gnayem & Sasson, 2013). The mixture, noted as solution A, was stirred for another hour. Meanwhile, 0.850 g of  $\text{AgNO}_3$  was dissolved in 940 mL of DI water in a 1-L flask. Then, solution A was added to the aqueous  $\text{AgNO}_3$  solution to form AgCl/BiOCl and the suspension was stirred for 6 h. The precipitate was collected by filtration

through a glass fiber filter (Whatman GF/C, 1.2  $\mu\text{m}$  pore size, also used for all other filtrations in this research) then redispersed in 1 L of DI water before being irradiated under 419 nm for 1 h to give Ag/AgCl/BiOCl suspension. The obtained particles were collected by filtration and washed thoroughly five times with ethanol and five more times with DI water; each washing step was followed by filtration. Finally, the washed Ag/AgCl/BiOCl was dried at 80°C for 8 h to produce a final photocatalyst which was subject to the following characterizations. X-ray diffraction (XRD) was performed on a Philips X'Pert MPD system with Cu K $\alpha$  radiation (45 kV). Ultraviolet-visible diffuse reflectance spectrum (UV-Vis DRS) was obtained using a Cary 300 UV-Vis spectrophotometer equipped with an Agilent DRA-CA-30I as an internal solid sample holder. Scanning electron microscopy (SEM) was performed using JEOL JSM-7600F.

#### **4.2.3. Synthetic produced water preparation**

Synthetic produced water preparation was the same as described in subsection 3.2.4.

#### **4.2.4. Photocatalytic experiment**

In a 35-mL test tube, 30 mL of sample and 150 mg (5 g/L) of photocatalyst (except in the effect of photocatalyst loading experiment, the amount of photocatalyst varied as described below) were placed. The mixture was stirred in the dark for 30 min to reach adsorption-desorption equilibrium. Prior to the photocatalytic reaction, 3 mL of sample was withdrawn for GA quantification of which the concentration was recorded as  $C_0$ . Photocatalytic degradation was conducted in a Rayonet RPR-200 photochamber which was equipped, in most of the experiment with 16 RPR-4190A lamps with primary illumination at 419 nm and 224 W in power. In the effect of light source experiment, 16 UV lamps (RPR-3500A) providing 350 nm irradiation were used with the same wattage as 419 nm.

During the photocatalytic reaction, a test tube was placed and stirred in the middle of the chamber. An aliquot of 3 mL was sampled from the solution every 15 min to study removal efficiency and kinetics of GA photodegradation. The temperature in the chamber during the experiment was controlled at  $< 40^{\circ}\text{C}$  during the operation by a cooling fan under the chamber. After the sampling, all aliquots of the suspension were centrifuged at 3,000 rpm for 10 min and the supernatant was used for GA analysis. Photocatalysis under natural sunlight was conducted on a bright sunny day of July 25, 2016, for 2 h from 1:00 PM to 3:00 PM. The location of the experiment was next to Civil and Industrial Engineering Building, North Dakota State University, Fargo, North Dakota, USA. A monthly average of solar energy at the point in July is  $7.86 \text{ kWh/m}^2/\text{day}$  (NASA, 2017).

The effects of photocatalyst loading (2, 5 and 8 g/L), initial GA concentration (0.1, 0.2 and 0.4 mM), salt concentration (0, 100, 200, 250 and 300 g/L), and pH (5, 6, 7, 8, and 9), and light source (419 nm, 350 nm and natural sunlight), on photocatalysis performance were examined. For GA photocatalytic degradation mechanism investigation, IPA, BQ, and TEOA were added to the sample at 1 mM to quench  $\bullet\text{OH}$ ,  $\text{O}_2^{\bullet-}$ , and  $\text{h}^+$  (holes), respectively. Each photocatalytic experiment described above was carried out in triplicate.

#### **4.2.5. GA quantification**

GA quantification is the same as described in subsection 3.2.4.

#### **4.2.6. Total organic carbon**

The TOC analysis was performed according to a method in subsection 3.2.5.

#### **4.2.7. Statistical analysis**

One-way analysis of variance (ANOVA) test was performed using Minitab software (version 18.1, 2017) with the posthoc Tukey Test to compare the kinetics of GA removal within

each treatment (photocatalyst dosage, pH, GA initial concentration, salt concentration, light sources, and quenchers). The significance criterion ( $\alpha$ ) is 0.05. The detailed results of ANOVA and Tukey Test are provided in Appendix, Tables A.18-A.23.

### **4.3. Results and discussion**

#### **4.3.1. Characteristics of Ag/AgCl/BiOCl**

The crystallinity, morphology and optical property of the prepared photocatalyst were measured by XRD, SEM, and UV-Vis DRS. The XRD patterns of prepared BiOCl and AgCl, as shown in Figure 4.1a, matched well with the standard patterns of tetragonal BiOCl (JCPDS no. 06-0249) and cubic AgCl (JCPDS no. 06-0480). The diffraction patterns of the BiOCl and AgCl also exhibit high intensity and were without any impurity peak. This observation suggests high phase purity of the sample. However, the diffraction peaks assigned for  $\text{Ag}^0$  were low, this could be due to its low content and high dispersity (Chen et al., 2015; Ye et al., 2012). Despite the difficulty in verifying the presence of  $\text{Ag}^0$  with the acquired XRD, the change in color of the suspension from white to grayish purple (Figure 4.1b) from partial photolysis of AgCl confirms the formation of  $\text{Ag}^0$ . UV-Vis DRS of Ag/AgCl/BiOCl (Figure 4.1c) indicates that the grayish purple Ag/AgCl/BiOCl can absorb all spectrum of visible light, which makes it a good photocatalyst for harnessing natural sunlight. From a SEM image shown in Figure 4.1d, BiOCl particles were flower-like microspheres with particle sizes ranging 2-5  $\mu\text{m}$ . The spots on the surface of the microspheres were Ag/AgCl.

**Figure 4.1.** (a) XRD patterns of the prepared Ag/AgCl/BiOCl photocatalyst. Vertical bars in the middle of the peaks represent the standard diffraction patterns from JCPDS files for BiOCl (no. 06-0249, red), AgCl (no. 06-0480, blue) and Ag (no. 04-0783, green). (b) Change in color of the prepared Ag/AgCl/BiOCl photocatalyst before and after irradiation. (c) UV-Vis DRS of the prepared Ag/AgCl/BiOCl photocatalyst. (d) SEM image of the prepared Ag/AgCl/BiOCl photocatalyst.

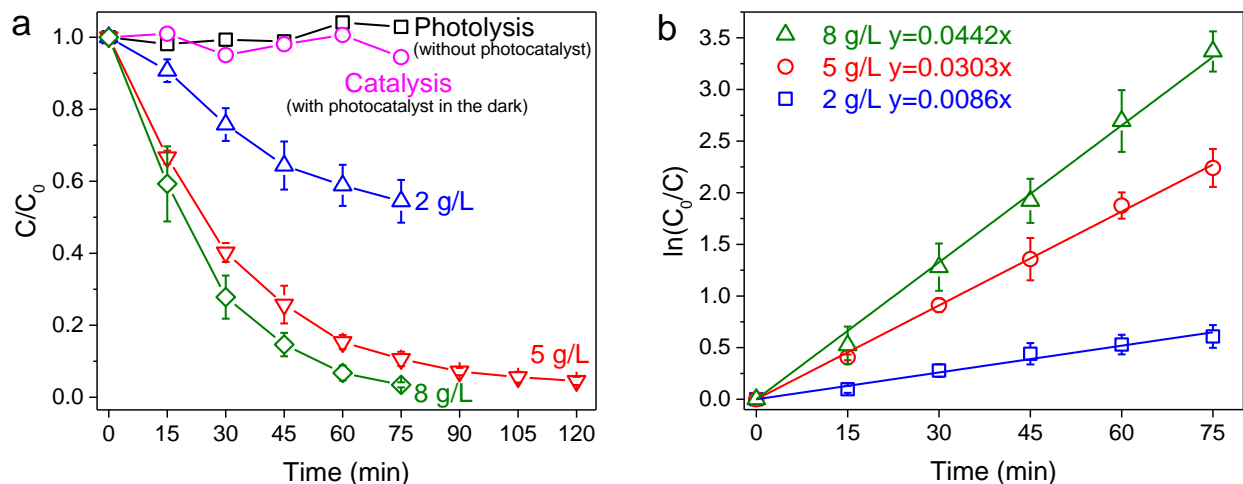

### 4.3.2. Photocatalytic reaction

#### 4.3.2.1. Effect of photocatalyst loading

Figure 4.2 shows the effect of photocatalyst loading on the disappearance of GA over time along with two controls – photolysis (sample was irradiated without adding the photocatalyst) and catalysis (suspension of photocatalyst and sample was kept the dark). There was no sign of GA degradation for both photolysis and catalysis. These results suggest that 419 nm light was not able to induce direct photolysis of GA and there was no reaction taking place between GA and the Ag/AgCl/BiOCl in the dark. The disappearance of GA in the presence of the photocatalyst (2, 5

and 8 g/L) and light, therefore, suggests that photocatalysis was taking place and served as the principal process behind this disappearance. At 5 g/L of the photocatalyst, about 95% of GA was removed after 120 min irradiation. However, the photocatalytic degradation of GA occurred mainly in the first 75 min (90% removal). Therefore, the irradiation time of 75 min was selected to study for other experiments including kinetics. At 75 min irradiation, the removal of GA markedly increased when the photocatalyst loading increased from 2 to 5 g/L (43 to 90%) but slightly improved from 5 to 8 g/L (90 to 97%).

The photocatalytic degradation of GA followed pseudo-first order reaction ( $R^2 > 0.99$ ) whereas other models (zero and second order) did not show any good regression. The rate constants ( $k_{obs}$ ) of GA photodegradation, which were all significantly different, were 0.0086, 0.0303, and 0.0442  $\text{min}^{-1}$  at 2, 5 and 8 g/L of the photocatalyst, respectively. Ag/AgCl/BiOCl have been reported to have high activity against methylene orange and rhodamine B at low photocatalyst loadings (0.2-1 g/L) (Xiong et al., 2011; Xu & Lin, 2016; Ye et al., 2012). However, high photocatalyst loadings (2-8 g/L) were used in this research due to the prolific water solubility of GA with minimal absorption on the photocatalyst surface, where the photocatalytic reaction occurs more efficiently. TOC removal at 5 g/L of photocatalyst was about 22% at 120 min irradiation. This value was much lower than GA removal (95%) suggesting limited mineralization of GA and formations of intermediate products.

**Figure 4.2.** Effect of Ag/AgCl/BiOCl loading on (a) removal efficiency, and (b) removal rate constant of GA.  $[GA]_0 = 0.1$  mM, pH = 7, NaCl = 200 g/L,  $\lambda = 419$  nm. Note: Corresponding GA concentrations can be found in Appendix Table A.24

#### 4.3.2.2. Effect of pH

pH alters the surface chemistry of the photocatalyst as well the aqueous chemistry of GA. These changes may affect the affinity of GA on the photocatalyst surface, and as a result affecting the decomposition rate of GA. The effect of pH from 5 to 9 (a typical range of pH of produced water) on GA photocatalysis was examined. The rate constant of GA degradation increased from 0.0013 to 0.0433  $\text{min}^{-1}$  when raising the pH from 5 to 9 (Figure 4.3). The degradation rate constants of GA were different at pH 5, 6, 7 and 9 but not statistically between pH 7 and 8, and pH 8 and 9. At pH 5, GA photodegradation rate constant was very low ( $k_{\text{obs}} = 0.0013 \text{ min}^{-1}$ ); however, the better result at this pH can be obtained by increasing photocatalyst loading (Figure 4.4). The dependence of GA rate constant on pH of the solution can be explained by the aqueous chemistry of GA itself. Under acidic conditions, GA is in a more hydrated form, whereas under alkaline conditions aldol condensation of GA is the predominant species. The aldol form of GA is more reactive and may possess stronger affinity to the photocatalyst than the hydrated form of GA. In addition, alkaline condition favors the formation of  $\bullet\text{OH}$  in the system through reaction of  $\text{h}^+$  with

more available  $\text{OH}^-$ . However, this may not be the case for the observed increase of GA degradation rate in this research. This is because if formed,  $\bullet\text{OH}$  was primarily consumed by predominant  $\text{Cl}^-$  in the sample leaving little amount for reaction with GA.

**Figure 4.3.** Effect of pH on the removal rate constant of GA. Sample pH was buffered by 10 mM phosphate.  $[\text{GA}]_0 = 0.1 \text{ mM}$ ,  $\text{NaCl} = 200 \text{ g/L}$ , photocatalyst  $5 \text{ g/L}$ ,  $\lambda = 419 \text{ nm}$ . Note: Corresponding GA concentrations can be found in Appendix Table A.25

**Figure 4.4.** Effect of Ag/AgCl/BiOCl loading on removal efficiency of GA at pH 5,  $[\text{GA}]_0 = 0.1 \text{ mM}$ ,  $\text{NaCl} = 200 \text{ g/L}$ ,  $\lambda = 419 \text{ nm}$ .

#### 4.3.2.3. Effect of salt concentration

The level of salt in produced waters varies greatly with the shale formation and location. It is, therefore, important to investigate the effect of salt concentration on GA photocatalysis. As

shown in Figure 4.5, when salt concentration increased, the photodegradation rate of GA decreased. This reduction could be from the changes in ionic strength of the solution. However, only a slight decrease in degradation rate over the range from 0 to 200 g/L of NaCl was observed. The degradation rate constants of GA at all salt concentrations were significantly different except between 100 g/L and 200 g/L of salt. At 250 g/L of NaCl, there was about 44% drop of the degradation rate compared to that at 200 g/L NaCl. At 300 g/L of NaCl, the photocatalytic decomposition of GA was completely inhibited. Again, the inhibition of GA removal by this high salt concentration can be overcome by increasing photocatalyst loading (Figure 4.6).

**Figure 4.5.** Effect of NaCl on removal rate constant of GA.  $[GA]_0 = 0.1$  mM, pH = 7, photocatalyst 5 g/L,  $\lambda = 419$  nm.

Note: Corresponding GA concentrations can be found in Appendix Table A.26

#### 4.3.2.4. Effect of initial GA concentration

The studied photocatalytic process was able to degrade GA efficiently at 0.1 mM (Figure 4.2a). Two higher initial concentrations of GA at 0.2 mM and 0.4 mM were experimented. There was about 50% reduction, which was statistically significant, of GA photodegradation rate for every two-fold increase in GA initial concentration (Figure 4.7). Upon irradiation, the photocatalyst generated reactive species that reacted with GA (see discussion on degradation

mechanisms in subsection 4.3.2.6). Regardless of the initial GA concentration, the generation of the reactive species was presumably the same. Therefore, when the initial GA concentration increased, there would be more competition for reactive species to react with GA molecules.

**Figure 4.6.** Effect of Ag/AgCl/BiOCl loading on removal efficiency of GA at NaCl = 300 g/L, [GA]<sub>0</sub> = 0.1 mM, pH = 7,  $\lambda$  = 419 nm.

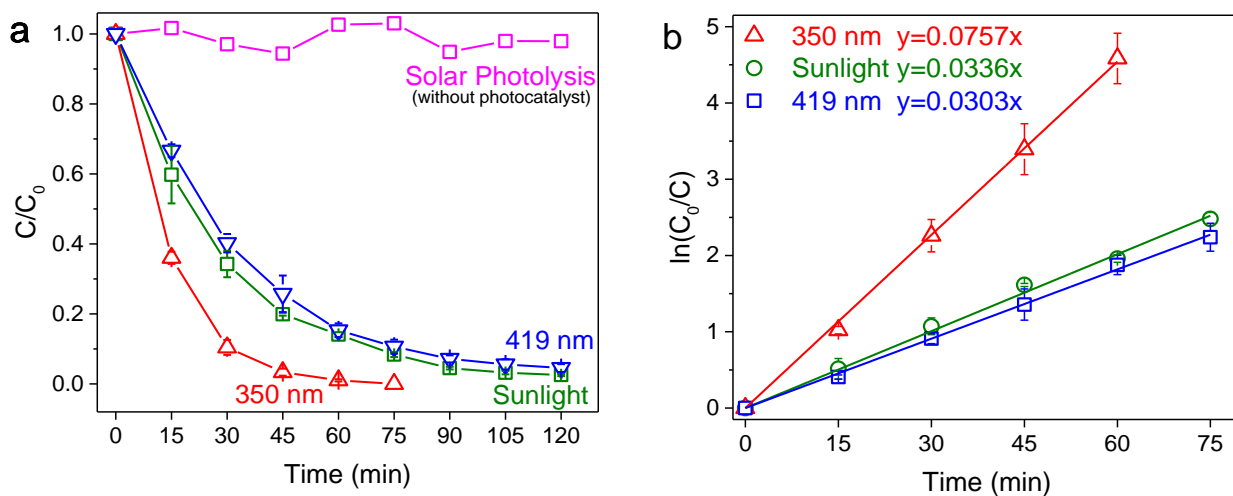

**Figure 4.7.** Effect of initial concentration on the removal rate constant of GA. NaCl = 200 g/L, pH = 7, photocatalyst 5 g/L,  $\lambda$  = 419 nm.

Note: Corresponding GA concentrations can be found in Appendix Table A.27

#### 4.3.2.5. Effect of light source

High reactivity under natural sunlight is one of the most desirable functionalities of semiconductor photocatalysts. In this experiment, the performance of the photocatalyst was tested under three different light sources: 419 nm (visible), 350 nm (UV) and natural sunlight (Figure 4.8). The removal rate of GA was significantly higher under UV with complete removal of GA after 60 min of irradiation compared to under visible light and natural sunlight, which provided similar rates. The performance of the photocatalyst under natural sunlight was very similar, except slightly better, to those under 419 nm in terms of GA removal efficiency and kinetics. Direct photolysis (without photocatalyst) of GA under natural sunlight was also conducted. There was no obvious loss of GA observed after 120 min irradiation. The stability of GA against natural sunlight is also reported in literature (Leung, 2001). For the same reason as explained previously, only irradiation time up to 75 min was used to study the kinetics. The rate constant of GA removal was the highest under 350 nm irradiation ( $0.0757 \text{ min}^{-1}$ ), followed by natural sunlight irradiation ( $0.0336 \text{ min}^{-1}$ ) and was the lowest under 419 nm irradiation ( $0.0303 \text{ min}^{-1}$ ).

**Figure 4.8.** Effects of light sources including natural sunlight on (a) removal efficiency, and (b) on removal rate constant of GA.  $[GA]_0 = 0.1 \text{ mM}$ ,  $\text{pH} = 7$ ,  $\text{NaCl} = 200 \text{ g/L}$ , photocatalyst  $5 \text{ g/L}$ . Note: Corresponding GA concentrations can be found in Appendix Table A.28

#### 4.3.2.6. Photocatalytic mechanism

Figure 4.9 shows the effect of quenchers on the removal of GA. IPA, TEOA and BQ at 1 mM were separately used to quench  $\bullet\text{OH}$ ,  $\text{h}^+$ , and  $\text{O}_2^{\bullet-}$ , respectively. The addition of IPA had a minor but statistically significant effect on GA photodegradation whereas pronounced reduction of GA removal was observed when BQ and TEOA was added, suggesting that  $\text{O}_2^{\bullet-}$  and  $\text{h}^+$  were the main reactive species responsible for the disappearance of GA. Alongside with direct reaction with contaminants, some generated  $\text{h}^+$  was also likely to oxidize  $\text{Cl}^-$  on the surface of AgCl and BiOCl to give  $\text{Cl}^\bullet$ , which also could oxidize GA (Xiong et al., 2011; Xu & Lin, 2016; Ye et al., 2012). During the reaction,  $\text{Cl}^\bullet$  was reduced back to  $\text{Cl}^-$ . Given the wide band gaps, AgCl and BiOCl cannot be activated by visible light (Ye et al., 2012), hence the adsorption of visible light of the photocatalyst was mainly from nano-Ag (n-Ag). Due to its surface plasmon resonance, n-Ag can strongly adsorb visible light and generate charge carriers ( $\text{e}^-$  and  $\text{h}^+$  pairs). Also a dipolar particle, n-Ag can efficiently hinder recombination of the  $\text{e}^-$  and  $\text{h}^+$  making them available for reaction (Wang et al., 2008).

**Figure 4.9.** Effects of active species quenchers on removal efficiency of GA.  $[\text{GA}]_0 = 0.1 \text{ mM}$ ,  $\text{pH} = 7$ ,  $\text{NaCl} = 200 \text{ g/L}$ , photocatalyst =  $5 \text{ g/L}$ ,  $\lambda = 419 \text{ nm}$ , time =  $75 \text{ min}$ ;  $[\text{IPA}]$ ,  $[\text{BQ}]$ ,  $[\text{TEOA}] = 1 \text{ mM}$ .

Note: Corresponding GA concentrations can be found in Appendix Table A.29

A schematic summary of the entire mechanisms is shown in Figure 4.10. Upon irradiation, n-Ag absorbed photon generating  $e^-$  and  $h^+$ . Then  $e^-$  was transferred to the conduction band of AgCl and BiOCl. The photogenerated  $e^-$  can reduce dissolved  $O_2$  to  $O_2^{\bullet-}$  (Wang et al., 2008). On the other hand, the photogenerated  $h^+$  was transferred to the surface of AgCl and BiOCl where it reacted with  $Cl^-$  to form  $Cl^{\bullet}$ . Together,  $h^+$ ,  $O_2^{\bullet-}$  and  $Cl^{\bullet}$  reacted with GA to form intermediates and final products. During the reaction,  $Cl^{\bullet}$  was reduced back to  $Cl^-$  again and again.

**Figure 4.10.** Proposed photocatalytic mechanisms of Ag/AgCl/BiOCl on GA.

#### 4.4. Summary

Visible light photocatalysis by Ag/AgCl/BiOCl is a promising technology for removing GA in produced water due to its exceptional performance under sunlight irradiation. High photocatalytic activity under sunlight is desirable since it provides free energy for irradiation, more importantly when prolonged irradiation is needed. The results from this research suggested that the performance of GA photodegradation increased when the concentration of photocatalyst increased, the concentration of NaCl decreased, the pH of the solution increased, the initial concentration of GA decreased, and when UV light was used instead of visible light. Under some conditions such as acidic solutions ( $pH \leq 5$ ) or high salt concentrations ( $NaCl \geq 300$  g/L), photocatalysis of GA could be hindered. However, this hindrance could be overcome by increasing

photocatalyst loading (8 g/L). Experiments on mechanism revealed that the  $h^+$  and  $O_2^{\bullet-}$  as well as  $Cl^{\bullet}$ , which was widely believed to form during irradiation, were the main reactive species involving in GA photocatalysis.

## 5. CONCLUSIONS AND RECOMMENDATIONS FOR FUTURE WORK

### 5.1. Conclusions

GA has been used extensively as a biocide in hydraulic fracturing fluid leading to its presence in oil and gas produced water. In this thesis research, UV photolysis and photocatalysis were used to degrade GA from brine solutions simulating produced water.

For photolysis, at studied conditions, GA removal efficiency was 52 to 85% within one hour irradiation. Photolysis of GA followed pseudo-first order kinetics. High salt concentrations ( $> 200$  g/L) increased the removal rate of GA, making photolysis suitable for GA removal in produced water, which typically contains high salt concentration (up to 400 g/L). Oligomers were identified as the main photolytic byproducts. GA photolytic pathways followed photolysis of the free aldehyde form of GA to generate free radicals that subsequently reacted with hydrated forms of GA to form oligomers.

For photocatalysis, Ag/AgCl/BiOCl was used as a visible light driven photocatalyst for removing GA in produced water. GA could be removed under both simulated visible light and under sunlight irradiation. High photocatalytic activity under sunlight is desirable since it provides free energy for irradiation, more importantly when prolonged irradiation is needed. In addition, GA could also be degraded at pH 5-9 and salinity 0-300 g/L (as NaCl) that are the typical ranges for actual produced water. However, under acidic conditions ( $\text{pH} \leq 5$ ) or high salinity ( $\text{NaCl} \geq 300$  g/L), which caused the pronounced interference to GA photodegradation, addition of photocatalyst loading (up to 8 g/L) were required. Charge carriers ( $\text{h}^+$  and  $\text{e}^-$ ) generated from the excited photocatalyst were primarily responsible for the degradation of GA. These charge carriers directly reacted with GA and/or induced the production of other reactive species such as  $\text{Cl}^\bullet$  and  $\text{O}_2^\bullet$  that

could also oxidize GA. In this study, the ability of Ag/AgCl/BiOCl under visible light to degrade an organic pollutant in brine solutions is demonstrated for the first time.

The findings in this study indicate that photolysis and photocatalysis are promising technologies in removing GA in flowback and produced waters. This study helps in addressing an obstacle associated with produced water treatment and disposal. After removing GA from flowback and produced waters, biological treatment, which is economical, will become a viable option for treatment of the waters for potential hydraulic fracturing reuse, or will make the waters less harmful for disposal. The work also provides an effective treatment scheme for a common biocide in produced water.

## **5.2. Recommendations for future work**

In order to move toward the applications of photolysis and photocatalysis for removal of GA in produced water, the following topics should be investigated.

1. Interferences of other contaminants found in actual produced water such as dissolved salts and other organics (surfactant, guar gum, and dissolved hydrocarbons) on the photolysis and photocatalysis of GA should be examined. These common chemicals may retard (react with ROS or compete for UV) or promote (photosensitizers) the efficiency of photolysis and photocatalysis.
2. Biodegradability and toxicity of GA and its products from both photolysis and photocatalysis should be tested.
3. Photoproducts from photocatalysis of GA should be identified in order to provide a deeper understanding of the degradation pathway.

Irradiated at 168 W	0.4500	0.5542	0.4928
Irradiated at 112 W	0.3156	0.3393	0.2653

**Table A.3.** GA Extinction Coefficient  $\lambda = 254$  nm,  $l = 1$  cm

Abs	C (M)	$\epsilon$ (L/mole cm)
0.057	0.0025	22.8
0.112	0.005	22.4
0.227	0.01	22.7
0.457	0.02	22.85
1.138	0.05	22.76
Average		22.702
In $\text{cm}^2/\text{mole}$		22702

GA extinction coefficient was calculated using Beer-Lambert Law:  $A = \epsilon \times C \times l$   
 Where: A = absorbance, C = concentration (M) and l = path length

**Table A.4.** One-way ANOVA test result for the effect of light intensity on photolysis of GA

ANOVA						
	Source	DF	Adj SS	Adj MS	F-Value	P-Value
	Factor	2	0.000263	0.000131	89.96	0.000
	Error	6	0.000009	0.000001
